AI in Space: A First Autonomous Rendezvous Simulation

Fabio Facin

May 2026

Abstract

This note records the first working version of an AI-in-space project. The first problem is small on purpose: a chaser spacecraft in low Earth orbit tries to rendezvous with a target by choosing from five simple thrust actions. The goal is not to claim a finished autonomy system. The goal is to build a loop we can inspect: propagate the orbit, choose an action, measure the result, and compare that behavior against later learning agents. The current baseline uses a short-horizon scoring rule, which I call the Rendezvous Intent Functional. I also add an early tabular Q-learning scaffold and a randomized-scenario test, which immediately shows the difference between solving one setup and learning behavior that generalizes.

1 Motivation

The goal of this project is to build an extensible simulation environment where spacecraft autonomy can be tested under increasingly realistic physical constraints. I am not starting with a neural network because that would hide too much too early. The first version should be something I can understand, break, and improve without guessing what the model learned. For that reason, the first controller is a transparent lookahead rule. It is not elegant, and it is not final, but it gives the project a baseline that future agents have to beat.

This direction is useful because autonomous spacecraft will need to make decisions when direct human control is delayed, unavailable, or too slow. Examples include satellite inspection, debris avoidance, lunar logistics, asteroid missions, deep-space navigation, and high-power electric propulsion missions. The long-term version of this project should let an agent reason about orbit, fuel, power, heat, sensor uncertainty, communication delay, radiation, and mission risk. For now, the right move is to get the small rendezvous problem working cleanly.

2 First Scenario

The first scenario is planar autonomous rendezvous. There are two spacecraft:

- a target spacecraft in a circular orbit at altitude 500 km,
- a chaser spacecraft in a nearby circular orbit at altitude 485 km, initially behind the target by 0.045 rad.

This fixed setup is the starter case. After the first successful run, I added randomized scenarios where the target altitude, chaser altitude offset, and starting phase angle vary. That randomized version is more important for learning because a policy can no longer survive by memorizing one trajectory.

The Earth gravitational parameter is

$$\mu_E = 398600.4418 \text{ km}^3/\text{s}^2,$$

and the Earth radius used in the simulation is

$$R_E = 6378.137 \text{ km}.$$

The target and chaser orbital radii are therefore

$$r_T = R_E + 500 = 6878.137 \text{ km}, \qquad r_C = R_E + 485 = 6863.137 \text{ km}.$$

For a circular orbit, the speed is

$$v = \sqrt{\frac{\mu_E}{r}}.$$

This gives

$$v_T = 7.6126 \text{ km/s}, \qquad v_C = 7.6209 \text{ km/s}.$$

3 Dynamics Model

The first model uses two-body orbital dynamics with an optional thrust acceleration:

$$\ddot{\mathbf{r}} = -\mu_E \frac{\mathbf{r}}{\|\mathbf{r}\|^3} + \mathbf{a}_T.$$

Here $\mathbf{r} \in \mathbb{R}^2$ is the spacecraft position vector, and $\mathbf{a}_T$ is the commanded thrust acceleration. The target spacecraft is propagated with $\mathbf{a}_T = \mathbf{0}$. The chaser may choose one of five discrete actions:

$$\mathcal{A} = \{\text{coast}, \text{prograde}, \text{retrograde}, \text{radial-out}, \text{radial-in}\}.$$

The maximum thrust acceleration in this first run is

$$a_{\max} = 2.0 \times 10^{-5} \text{ km/s}^2 = 0.02 \text{ m/s}^2.$$

The numerical propagator is fourth-order Runge–Kutta with timestep

$$\Delta t = 10 \text{ s}.$$

4 The First Custom Formula

At each decision time t_k, the agent evaluates every candidate action $a \in \mathcal{A}$. Each candidate action is held constant over a lookahead horizon

$$H = 900 \text{ s}.$$

Let the relative position and velocity after the lookahead be

$$\boldsymbol{\rho}_H(a) = \mathbf{r}_C(t_k + H; a) - \mathbf{r}_T(t_k + H),$$

$$\boldsymbol{\nu}_H(a) = \mathbf{v}_C(t_k + H; a) - \mathbf{v}_T(t_k + H).$$

Let the closest predicted distance during the lookahead be

$$d_{\min}(a) = \min_{\tau \in [0,H]} \|\mathbf{r}_C(t_k + \tau; a) - \mathbf{r}_T(t_k + \tau)\| .$$

The first decision formula for this project is the **Rendezvous Intent Functional**:

$$\boxed{\mathcal{J}_{\mathrm{RIF}}(a; t_k) = \|\boldsymbol{\rho}_H(a)\| + \lambda_v \|\boldsymbol{\nu}_H(a)\| + \lambda_c d_{\min}(a) + \lambda_f \Delta v_a}$$

The selected action is

$$a^*(t_k) = \arg\min_{a \in \mathcal{A}} \mathcal{J}_{\mathrm{RIF}}(a; t_k).$$

4.1 Meaning of Each Term

The term $\|\boldsymbol{\rho}_H(a)\|$ rewards actions that reduce the predicted range to the target after the lookahead horizon.

The term $\lambda_v \|\boldsymbol{\nu}_H(a)\|$ penalizes high relative velocity. This matters because rendezvous is not just about getting close; the chaser must also arrive gently enough to remain controllable.

The term $\lambda_c d_{\min}(a)$ is a first-pass closeness-seeking term. In this initial no-debris scenario, smaller closest approach is useful, so this term helps the planner prefer actions that create an actual rendezvous opportunity. In future debris or docking scenarios, this term should be replaced or combined with a safety barrier that penalizes being too close at unsafe speeds.

The term $\lambda_f \Delta v_a$ penalizes fuel use. For a constant burn over the lookahead horizon,

$$\Delta v_a = \begin{cases} 0, & a = \text{coast}, \\ a_{\max} H, & a \neq \text{coast}. \end{cases}$$

The current simulation uses the unnormalized implementation

$$\mathcal{J}_{\mathrm{run}}(a; t_k) = D_H(a) + 900 V_H(a) + 0.2 D_{\min}(a) + C_f(a),$$

where D_H is in kilometers, V_H is in kilometers per second, and C_f is a small burn penalty. This is not meant to be the final objective function. It is the first testable version: simple enough to debug, but structured enough to evolve.

5 What We Are Testing

This first paper tests four basic ideas:

1. whether a short-horizon action evaluator can reduce target distance without being explicitly taught a Hohmann transfer,
2. whether relative velocity can be included in the same formula as position error,
3. whether the same physics can be implemented consistently in Python and C++,
4. whether this formula gives us a foundation that can later become a reinforcement learning reward or model predictive control objective.

6 Fixed-Scenario Result

The first simulation ran for up to 7200 s, with a new decision every 60 s. The success condition was

$$\|\boldsymbol{\rho}\| \leq 5 \text{ km} \qquad \text{and} \qquad \|\boldsymbol{\nu}\| \leq 0.020 \text{ km/s}.$$

Quantity	Value
Initial range	309.52 km
Final range	4.89 km
Minimum range	4.89 km
Final relative speed	0.0128 km/s
Approximate Δv used	80.6 m/s
Simulated time to success	90.2 min

Table 1: First autonomous rendezvous result using the Rendezvous Intent Functional.

7 Randomized Scenarios and Q-Learning

After the fixed case worked, I converted the Python simulation into a small reinforcement-learning-style environment with `reset()` and `step(action)`. The first learning agent is deliberately modest: a tabular Q-learning policy with discretized relative geometry, relative velocity, fuel remaining, and decision time. It is warm-started from the greedy planner, so it should be treated as a learning scaffold rather than an independent solution.

The important change is that the environment can now randomize the target altitude, chaser altitude offset, and initial phase angle. This immediately made the problem more honest. The greedy planner still gives a useful baseline, but the Q table struggles to generalize across randomized starts.

Quantity	Value
Randomized evaluation cases	24
Q-learning successes	1
Success rate	4.2%
Mean final range	136.33 km
Best final range	4.95 km
Mean final relative speed	0.1523 km/s
Mean approximate Δv	84.20 m/s

Table 2: Early randomized-scenario evaluation for the warm-started tabular Q-learning policy.

One randomized replay is still encouraging. For seed 10024, the Q-learning policy succeeds:

The visual replay matters here. In that seed, the chaser appears to catch up to the target path instead of simply diving inward. The action mix is also different from the fixed greedy case: 165 coast steps, 300 radial-in steps, 54 radial-out steps, and 30 retrograde steps. That looks like the beginning of a reusable rendezvous pattern, but the low overall success rate shows that the policy does not yet know when to use that pattern.

Figure 1: Target and chaser trajectories for the first autonomous rendezvous attempt.

8 Discussion

The result is promising because a very simple action evaluator was able to reduce range from roughly 310 km to under 5 km while satisfying the relative-speed constraint. This does not mean the agent is intelligent in the final sense. It means the project now has a working decision loop:

$$\text{state} \rightarrow \text{candidate actions} \rightarrow \text{physics rollout} \rightarrow \text{score} \rightarrow \text{chosen action}.$$

That loop is exactly what we need before serious reinforcement learning. The randomized tests also show why the baseline matters. One successful Q-learning replay can look good, but the multi-seed evaluation tells the truth: the current learner is not robust yet. That is useful, because now the project has a way to measure progress instead of only producing good-looking animations.

9 Next Steps

The next version should introduce a normalized objective:

$$\tilde{\mathcal{J}}(a; t_k) = w_r \frac{\|\boldsymbol{\rho}_H(a)\|}{r_{\text{ref}}} + w_v \frac{\|\boldsymbol{\nu}_H(a)\|}{v_{\text{ref}}} + w_f \frac{\Delta v_a}{\Delta v_{\text{ref}}} + w_s B(a),$$

Figure 2: Relative distance between the chaser and target over time.

Quantity	Value
Final range	4.95 km
Final relative speed	0.0146 km/s
Approximate Δv used	76.80 m/s
Simulated time to success	91.3 min

Table 3: Successful randomized Q-learning replay for seed 10024.

where $B(a)$ is a safety barrier term. For example, a future debris-aware version could use

$$B(a) = \sum_i \frac{1}{\max(d_i(a) - d_{\text{safe}}, \epsilon)^2},$$

where $d_i(a)$ is the predicted distance to object i, d_{safe} is the required safety distance, and ϵ prevents division by zero.

The immediate AI work is more specific:

- improve the state bins for radial position, along-track position, radial velocity, and along-track velocity,
- adjust the reward so the agent learns controlled closing speed instead of only reducing distance,
- train on a wider but staged set of randomized scenarios,
- compare every learner against the greedy planner, the random policy, and the fixed-scenario baseline.

After that, the project should add:

- debris avoidance,

- sensor noise,
- continuous thrust,
- low-thrust electric propulsion,
- battery and reactor power constraints,
- thermal/radiator limits,
- reinforcement learning agents trained against the same environment.

10 Conclusion

This first paper defines the foundation of the AI in Space project, but it should be read as a lab note, not a finished result. The first simulation is deliberately small, but it already combines orbital mechanics, numerical integration, autonomous action selection, measurable success criteria, and visual replay. The Rendezvous Intent Functional is the first custom formula in the project. It is not final; it is a testable starting point. The randomized Q-learning result is the more important lesson: the system can produce a successful learned-looking replay, but it does not yet generalize reliably. That is the next problem to solve.

11 Long-Term Aim: The Spacecraft Autonomy Functional

The long-term aim of this project is to move from a rendezvous-only score to a general mission decision formula. The formula below is not something this first simulation has proven. Instead, it is the direction we are aiming toward: a single objective that lets an autonomous spacecraft balance mission progress, fuel, safety, power, heat, uncertainty, and timing.

We call this target formula the **Spacecraft Autonomy Functional**:

$$\boxed{\begin{aligned}\mathcal{J}_{\mathrm{SAF}}(a;t) = {} & w_m \Phi_{\mathrm{mission}}(x_{t+H}) + w_r \frac{\|\boldsymbol{\rho}_H(a)\|}{r_{\mathrm{ref}}} + w_v \frac{\|\boldsymbol{\nu}_H(a)\|}{v_{\mathrm{ref}}} + w_f \frac{\Delta v_a}{\Delta v_{\mathrm{ref}}} \\ & + w_p \frac{P_{\mathrm{req}}(a)}{P_{\mathrm{avail}}} + w_q \frac{Q_{\mathrm{thermal}}(a)}{Q_{\mathrm{limit}}} + w_s \mathcal{B}_{\mathrm{safety}}(a) + w_u \mathrm{tr}(\Sigma_{t+H}(a)) + w_\tau \left| \frac{\Delta \tau_{\mathrm{rel}}(a)}{\tau_{\mathrm{ref}}} \right| .\end{aligned}}$$

The autonomous spacecraft should choose

$$a^*(t) = \arg\min_{a \in \mathcal{A}} \mathcal{J}_{\mathrm{SAF}}(a;t).$$

Each term represents a future research layer:

- Φ_{mission}: mission progress, such as inspection completion, docking readiness, transfer accuracy, or cargo delivery.
- $\|\boldsymbol{\rho}_H\|/r_{\mathrm{ref}}$: normalized future position error.
- $\|\boldsymbol{\nu}_H\|/v_{\mathrm{ref}}$: normalized future relative velocity error.
- $\Delta v_a/\Delta v_{\mathrm{ref}}$: normalized propellant or maneuver cost.

- $P_{\text{req}}/P_{\text{avail}}$: power demand relative to available spacecraft power.
- $Q_{\text{thermal}}/Q_{\text{limit}}$: thermal load relative to radiator or component limits.
- $\mathcal{B}_{\text{safety}}$: collision, keep-out-zone, radiation, or hardware-limit barriers.
- $\text{tr}(\Sigma_{t+H})$: predicted navigation uncertainty, where Σ is the state-estimation covariance.
- $\Delta\tau_{\text{rel}}/\tau_{\text{ref}}$: relativistic timing correction, useful later for precision navigation and clock-sensitive missions.

This formula gives the project a north star. The first Rendezvous Intent Functional is a small subset of it. As the simulator grows, each term can become a separate experiment: first orbital motion, then collision safety, then uncertainty, then power and thermal constraints, then nuclear-electric propulsion, and eventually relativistic navigation corrections.
